TESTS OF A ROMAN POT PROTOTYPE FOR THE TOTEM EXPERIMENT

Abstract

The TOTEM collaboration has developed and tested the first prototype of its Roman Pots to be operated in the LHC. TOTEM Roman Pots contain stacks of silicon detectors with strips oriented in two orthogonal directions. To measure proton scattering angles of a few microradians, the detectors will approach the beam centre to a distance of 10σ/0.5 mm (= 1.3 mm). Dead space near the detector edge is minimised by using two novel “edgeless” detector technologies. The silicon detectors are used both for precise track reconstruction and for triggering. The first full-sized prototypes of both detector technologies as well as their read-out electronics have been developed, built and operated. The tests took place in the proton beam-line of the SPS accelerator ring. In addition, the pot’s shielding against electromagnetic interference and the longitudinal beam coupling impedance have been measured with the wire method.

ROMAN POTS FOR THE TOTEM EXPERIMENT AT LHC

The LHC experiment TOTEM [1] is designed for measuring the elastic pp scattering cross-section, the total pp cross-section and diffractive processes. These physics objectives require the detection of leading protons with scattering angles of a few µrad, which is accomplished with a Roman Pot (“RP”) system having stations at 147 m and 220 m from the interaction point 5 where CMS will be located. Each station is composed of two RP units separated by 2.5 – 4 m depending on beam equipment integration constraints. Each RP unit consists of a vacuum chamber equipped with two vertical insertions (top and bottom) and a horizontal one. Each insertion (“pot”) contains a package of 10 silicon detectors in a secondary vacuum. The pots can be moved into the primary vacuum of the machine through vacuum bellows. In order to minimize the distance of the detectors from the beam, and to minimize multiple scattering, the wall thickness of the pot is locally reduced to a thin window foil (140 – 210 µm).

The low impedance budget of the LHC machine (broadband longitudinal impedance limit Z/n ≈ 0.1 Ω) imposes a tight limit on the RPs’ beam coupling impedance. Because of the beam’s bunch structure and its high intensity, the pick-up noise on the detector electronics caused by electromagnetic leakage is a potential concern and needs to be studied and minimised.

THE ROMAN POT PROTOTYPE IN THE SPS BEAM

During the summer 2004 the TOTEM collaboration has performed tests on a prototype unit made of 2 vertical RPs. The unit has been installed in the LSS5 section of the SPS accelerator at CERN. The motors moving the pots towards the beam, the electronics of the detectors and the cooling system stabilising the temperature of the detectors inside the pots were operated remotely from a temporary control room in a surface building. The upper and lower pots contained each a set of 8 silicon strip detectors with 66 µm pitch, built in two novel technologies allowing for efficiency up to the physical edge [1]. Six of them were read out with analogue APV25 chips and 2 with digital VFAT chips delivering the fast-or signal of all 512 strips. The latter were used for triggering the data acquisition system in coincidence with the sum signal of the four pick-up electrodes of a beam position monitor.

In the retracted pot position the thin windows were 40 mm away from the beam pipe axis. To watch the effect of the RPs’ movements on the beam quality, three beam loss monitors (BLMs) have been installed near the unit: one at 56 cm upstream on the top of the beam pipe and two at 65 cm downstream, one on the top and one on the bottom of the pipe. The BLMs used were cylindrical ionisation chambers filled with air.

TOTEM was the SPS main user during 2 shifts of 8 hours with dedicated coating beam. Three bunch structures were tested: 1 single bunch in the ring, 4 bunches equally spaced, and 4 equally spaced trains of 4 bunches.

Detector data were taken with the two pots positioned independently between 6 mm and 14 mm (σbeam ≈ 0.8 mm).
from the beam pipe centre. Because of contact problems with the Kapton connections between the individual detector/chip hybrids and the central electronics board of each pot, 4 out of the 16 detectors could not be read out. The high redundancy in the system’s design however allowed us to carry out the experiment as planned.

The observed variation of the rate with the distance is not big because all measurements were made more than $8\sigma$ from the beam centre where the halo is rather flat.

The response of the tracking silicon detectors conforms to expectations. Figure 3 shows the halo profiles measured by detector planes with orthogonal strip orientations.

**LABORATORY MEASUREMENTS OF THE RF BEHAVIOUR**

For the measurements of the pot’s radiofrequency behaviour a 0.3 mm thick wire was strung through the RP along its beam axis.

![Figure 4: Setup for the laboratory measurements. For the connections see text.](image)

**Attenuation of Electric and Magnetic Fields by the Roman Pot Window**

To determine the attenuation of electromagnetic fields by the RP’s windows, the silicon detectors were replaced with antenna insertions (Figure 4). A network analyser measured the transmission from one end of the RP (Port A) to each of the antenna outputs (Ports 1 to 4) for frequencies up to 200 MHz. The other end of the RP (Port B) was...
terminated with 50 Ω. The transmitted signal was amplified by 30 dB. The top and bottom insertions had 210 μm and 140 μm thick windows respectively. To measure the pure signal coupling between the wire and the antennas, comparison measurements without any window have been made. The results for a distance of 2 mm are shown in Figure 5. The transmitted electric field is mostly smaller than approximately Gaussian LHC bunch structure with given in Figure 8 for the two main resonances. The approximation measurements without any window have been made. The results for a distance of 2 mm are shown in Figure 5. The transmitted electric field is mostly smaller than 60 dB. The influence of bunch-generated fields on detectors and electronics remains to be measured in the future with a spark generator.

![Figure 5: Signal transmission from the wire to the antennas as a function of the frequency for a distance of 2 mm between each pot and the wire in the centre. The peaks at 160 MHz are caused by a resonance of the pin probe. Corrections for reflections at Port A and for the 30 dB amplification have been applied.](image1)

**The Longitudinal Beam Coupling Impedance**

To determine the longitudinal beam coupling impedance $Z$, the complex transmission coefficient $S_{21}$ between Ports A and B (Figure 4) was measured with a network analyser. Then $Z$ was calculated from $S_{21}(f, d)$ with the RP at a distance $d$, and a reference measurement $S_{21}^{ref}(f)$ with the RP in retracted position. The “improved log formula” proposed by Shaposhnikova and Jensen [2]

$$Z(f, d) = -2Z_C \ln \frac{S_{21}(f, d)}{S_{21}^{ref}(f)} \left[1 + i \ln \frac{S_{21}(f, d)}{S_{21}^{ref}(f)} \frac{1}{4\pi l f/c} \right]$$

was used, where $Z_C = 294 \Omega$ is the characteristic impedance of the unperturbed beam pipe, $l = 11$ cm is the length of the perturbation (i.e. the diameter of the pot insertions), and $f$ is the frequency. The dash-dotted line in Figure 7 shows the real part of $Z$ for $d = 2$ mm with the original configuration of the RP. The dependence on $d$ is given in Figure 8 for the two main resonances. The approximately Gaussian LHC bunch structure with $\sigma_t = 0.25$ ns leads to a Gaussian envelope with $\sigma_f = 0.63$ GHz in the frequency distribution of the LHC current with harmonics every 40 MHz. Hence the relevant resonances lie well below 1 GHz. The dominant line at 740 MHz has an impedance of 1.2 kΩ which yields an uncomfortably high $Z/n = 18$ mΩ where $n = f_{reson}/f_{LHC} = 740$ MHz/11 kHz. After installation of little pieces of ferrite into the cavity around the RP insertion, this impedance is damped by a factor 5, demonstrating the effectiveness of the ferrite approach. For the final RP the geometrical ferrite arrangement will be optimised to further reduce the impedance.
