I. Abstract

The feasibility of extracting particles from the halo of a circulating proton beam using a bent silicon crystal has been demonstrated experimentally at the SPS for a beam energy of 120 GeV. Presently studies are conducted to understand the extraction mechanisms and the measured efficiencies. In particular the contribution of multi-pass extraction, where the particles can pass through the crystal many times before being channeled and extracted, is investigated. In a recent experiment, using a crystal especially fabricated with a finite amorphous layer on its surface, it has been proven that multi-pass extraction plays an important role. The experiment is described and the implication for further studies are discussed.

II. INTRODUCTION

There is considerable theoretical and experimental activity in order to understand the mechanisms leading to the observed proton beam intensities extracted by means of a bent crystal from high energy accelerators [1], [2], [3], [4]. One aim of this work is to assess the perspectives of using such a crystal to parasitically extract a proton beam from the LHC [5].

While the principles of channeling and deflection of protons in bent silicon crystals are well understood [6], the specific processes leading to the extraction of protons from the halo of a circulating beam are more difficult to assess. The extraction of 120 GeV protons from a beam coasting in the CERN SPS is now regularly achieved with an efficiency of about 10% [3]. Two mechanisms are being discussed, which could be responsible for extraction with a bent crystal: first-pass extraction and multi-pass extraction. The aim of the experiment described in this report was to experimentally demonstrate the existence of the latter.

III. EXPERIMENT AT THE SPS

For the present experiment a 120 GeV coasting beam with an intensity of about $5 \cdot 10^{11}$ protons was used. The lifetime of the beam without external interference can be several hundred hours. The crystal is placed typically at 10 from the closed orbit, some 10 times the transverse beam size, where only very few halo particles are found initially. The beam is then excited horizontally with band limited white noise induced on a pair of condenser plates. Typical kicks produced are of order 0.0005 - 0.005 mrad, and the kick strength can be varied by changing the noise amplitudes. Once the beam has diffused onto the crystal and a steady state is reached, normalized emittances of 60 mm mrad (horizontal) and 10 mm mrad (vertical, unaffected by the noise) are found. Beam lifetimes in this steady state vary from a few minutes to 50 hours depending on the kick strength. The protons extracted by the bent crystal are measured in an arrangement of detectors which is described in refs. [3], [4].

IV. FIRST- AND MULTI-PASS EXTRACTION

First-pass extraction would correspond to the experimental situation found at an external beam-line [6], the only difference being the small impact parameters of the protons onto the crystal (see next section). Therefore, for first-pass extraction the surface quality is of paramount importance.

Multi-pass extraction has been predicted as a possible mechanism by several authors [7], [8]. The term "multi-pass" refers to the situation of protons that are not channeled during their first encounter with the crystal, but rather scattered by a small angle. Thus these protons will have "further chances" at later turns to be channeled and extracted when passing the crystal inside the critical angle for channeling (see [3]) and with larger impact parameters. While for a first-pass extraction with the required high efficiency the surface properties of the crystal are important, the accelerator parameters play a more important role for the multi-pass mechanism [9].

No direct experimental proof of the existence of this mechanism existed so far, although some (model-dependent) conclusions were inferred from recent experimental results. For example, the observation of extracted protons over a very large range of crystal angles with respect to the closed orbit in the SPS experiment [3], but also the enhanced extraction efficiency due to an additional scatterer observed at Serpukhov [10] seem to indicate the importance of multi-pass extraction.

Within the restrictions of an accelerator experiment, the possibility to reach large impact parameters (therefore clear "first-pass" conditions) are limited: the only possibility found is the "kick-mode" [11], but the high instantaneous proton intensities extracted in this mode make it hard to estimate an extraction efficiency. Furthermore, such a mode does not reflect the standard operational conditions and certainly cannot be used for a parasitic extraction in the LHC. Therefore, a different approach was taken here to experimentally prove the importance of multi-pass extraction: a crystal as shown in Fig. 1, with an amorphous layer of 30 μm Silicon oxide, has been installed in the SPS [12].

This layer should prevent any first-pass extraction, the impact parameters being much smaller than the thickness of the layer (see below). An extracted beam would therefore demonstrate the existence of multi-pass extraction and provide a clean sample to study the multi-pass process separately and in detail.
proportionately linearly with the kick strength and scaling of the impact parameter distributions obtained is thus permitted. The important result at this stage is that the mean impact parameter (of an exponential distribution) in the experiment is estimated to be about 20 - 50 nm and excludes first-pass extraction.

VI. EXPERIMENTAL RESULTS

Results of the measurements using the bent silicon crystal with its amorphous layer are summarized in Table 1.

Table 1
Extraction efficiencies for the crystal with an amorphous layer.

Measurements were taken for different kick strengths and a crystal position 10 mm from the closed orbit [15]. The number of particle hitting the crystal is estimated from the beam intensity and the measured lifetime. Extraction efficiencies (defined as the ratio between extracted and lost particles) are rather independent of the kick strength (i.e. impact parameter b) and are in the same order of magnitude as found without amorphous layer [3]. From this result we conclude the existence of multi-pass extraction. The comparable efficiency also indicates that this mechanism plays an important role in the extraction process. The large thickness of the amorphous layer causes proton losses even on later turns, thus reducing the efficiency slightly. A typical angular scan obtained with this crystal is shown in Fig. 3. The width of the scan is approximately 300 μrad and the comparison with an angular scan for the same crystal without the amorphous layer shows a similar result [3] and further supports our conclusion that multi-pass extraction is a dominant mechanism. The profiles of the extracted beam as measured by the scintillator hodoscope at the peak of the angular scan are shown in Figs. 4 and 5. For comparison, measurements were also performed with a so-called “U-shaped” crystal (see [4]), and efficiencies of up to 16% have been found. Detailed results are published elsewhere [15].

VII. FURTHER STUDIES AND IMPROVEMENTS

Once the existence and importance of the multi-pass process is established, one can try to increase the extraction efficiency. It has been demonstrated [9] that the efficiency for pure multi-pass extraction strongly depends on the machine parameters, in particular on the β-function at the crystal position and the tune.
This can only be explained by a multi-pass extraction mechanism.

- The efficiency and angular scans are comparable to the one obtained without an amorphous layer and prove the importance of this mechanism for the extraction process.

VIII. CONCLUSION

We have investigated the mechanism of multi-pass extraction using a bent crystal with an imperfect surface and have made the following observations:

- We have measured extracted particles using a crystal with an amorphous layer of 30 $\mu$m.
